1 The generating functional

The central object of the functional approach to quantum field theory is the generating functional of correlation functions. For a single real scalar field $\phi(x)$ in four spacetime dimensions, every time-ordered vacuum expectation value can be obtained by differentiating a single functional of an external source $J(x)$. The philosophy mirrors that of statistical mechanics: just as the partition function encodes all thermodynamic information about a system in equilibrium, the generating functional encodes the complete set of Green functions of the theory.

The construction begins with the classical action. We take the standard Lagrangian density of a massive scalar with a quartic self-interaction, $\mathcal{L} = \frac{1}{2} \partial_\mu \phi \partial^\mu \phi - \frac{1}{2} m^2 \phi^2 - \frac{\lambda}{4!} \phi^4$, where m is the bare mass and λ the bare coupling. The factor of $1/4!$ is a convention that cancels the combinatorial factor arising from the four identical fields meeting at a vertex, so that the Feynman rule for the vertex is simply $-i\lambda$.

Coupling the field linearly to the source and integrating over all field configurations with appropriate boundary conditions yields the object we are after. Written as a formal path integral it reads as follows.

side the mass term selects the vacuum-to-vacuum amplitude. Functional derivatives of $\mathcal{Z}[J]$ with respect to the source pull down factors of the field: the n -point function is $\langle 0 | T \phi(x_1) \cdots \phi(x_n) | 0 \rangle = (-i)^n \delta^n \mathcal{Z} / \delta J(x_1) \cdots \delta J(x_n)$ evaluated at $J = 0$, up to the normalization $\mathcal{Z}[0]$.

Two related functionals are worth introducing immediately. The logarithm $W[J] = -i \ln \mathcal{Z}[J]$ generates only the *connected* Green functions, discarding the disconnected pieces that merely repeat lower-point information. Its Legendre transform $\Gamma[\varphi] = W[J] - \int d^4x J\varphi$, taken with respect to the classical field $\varphi(x) = \delta W / \delta J(x)$, generates the one-particle-irreducible vertices. It is Γ that satisfies the quantum-corrected equations of motion and whose second derivative is the full inverse propagator.

For the free theory, $\lambda = 0$, the integral is Gaussian and can be done exactly. Completing the square gives $\mathcal{Z}_0[J] = \mathcal{Z}_0[0] \exp(-\frac{i}{2} \int d^4x d^4y J(x) \Delta_F(x - y) J(y))$, where Δ_F is the Feynman propagator, the Green function of the Klein-Gordon operator with causal boundary conditions. In momentum space $\tilde{\Delta}_F(p) = i/(p^2 - m^2 + i\epsilon)$, and the pole at $p^2 = m^2$ identifies the mass of the free particle.

Everything hard about the interacting theory is

$$\mathcal{Z}[J] = \int \mathcal{D}\phi \exp\left(i \int d^4x \left[\frac{1}{2} \partial_\mu \phi \partial^\mu \phi - \frac{1}{2} m^2 \phi^2 - \frac{\lambda}{4!} \phi^4 + J\phi \right] \right) \quad (\text{full-width band, columns not balanced})$$

(1)

The measure $\mathcal{D}\phi$ denotes integration over all field configurations, and the $i\epsilon$ prescription hiding in-

contained in the quartic term. No closed form for

the integral is known in four dimensions, and the two systematic strategies available are the perturbative expansion in powers of λ , organized by Feynman diagrams, and non-perturbative evaluation on a space-time lattice. We follow the first route here, since it makes the combinatorial structure of the theory most transparent and connects directly to scattering experiments through the LSZ reduction formula.

Before expanding, one should appreciate what the generating functional already tells us at the formal level. Symmetries of the action become identities among Green functions: invariance of the measure and the action under $\phi \rightarrow -\phi$ forces every odd correlation function to vanish, so the perturbative series contains only even powers of the field. Translation invariance makes all correlators functions of coordinate differences, which is why momentum space is the natural arena. These exact statements survive renormalization and serve as checks on any explicit calculation.

2 Perturbative expansion

the counterterms required have the same form as the terms already present in the Lagrangian.

$$\mathcal{Z}[J] = \exp\left(-\frac{i\lambda}{4!} \int d^4x \left(\frac{1}{i} \frac{\delta}{\delta J(x)}\right)^4\right) \mathcal{Z}_0[J] = \sum_{V=0}^{\infty} \frac{1}{V!} \left(-\frac{i\lambda}{4!}\right)^V \left[\int d^4x \left(\frac{1}{i} \frac{\delta}{\delta J(x)}\right)^4\right]^V \mathcal{Z}_0[J] \quad (2)$$

The trick behind equation (??) is standard but worth spelling out. Inside the path integral, every factor of the field $\phi(x)$ can be generated by a functional derivative $\frac{1}{i} \delta/\delta J(x)$ acting on the source term. The interaction part of the exponential can therefore be pulled out of the integral as a differential operator acting on the free generating functional, which we computed exactly in the previous section. Expanding both exponentials produces a double series: V counts interaction vertices and the expansion of $\mathcal{Z}_0$ counts propagators.

Each term of the double series is a sum of Feynman diagrams. A diagram with V vertices, P propagators and E external sources contributes at order λ^V , with the propagators pairing up the $4V + E$ functional derivatives in all possible ways. Wick's theorem is nothing more than this counting of pairings. The $1/V!$ and the $1/4!$ per vertex are largely eaten by the number of equivalent pairings, leaving the residual symmetry factor of the diagram — the order of its automorphism group — in the denominator.

The first nontrivial effects appear at one loop. The two-point function receives the tadpole correction, a single propagator closed on itself and attached to one vertex, which shifts the mass. The four-point function receives the one-loop bubble in the s , t and u channels, which makes the effective coupling depend on the energy at which it is measured. Both diagrams are ultraviolet divergent, and the divergences are the entry point of renormalization theory.

In dimensional regularization one continues the loop integrals to $d = 4 - \epsilon$ dimensions, where they converge, and isolates the divergences as poles in $1/\epsilon$. The tadpole gives $\delta m^2 \propto \lambda m^2/\epsilon$ and the bubble gives $\delta\lambda \propto \lambda^2/\epsilon$. Both poles can be absorbed into a redefinition of the bare parameters, which is the statement that ϕ^4 theory is perturbatively renormalizable:

The price of the subtraction is the appearance of an arbitrary scale μ , and physical quantities can only be independent of it if the renormalized coupling runs. The one-loop beta function, $\beta(\lambda) = 3\lambda^2/16\pi^2 + O(\lambda^3)$, is positive: the coupling grows in the ultraviolet, and the theory is infrared free. The same calculation, with the sign flipped by the non-abelian gauge boson loops, is what produces asymptotic freedom in QCD; the scalar theory is the cleanest laboratory in which to learn the machinery.

The positive beta function has a famous consequence. Integrating the flow, the running coupling blows up at a finite energy, the Landau pole, signalling that the perturbative theory cannot be a complete description up to arbitrarily high scales. Lattice studies strengthen this into the triviality scenario: in four dimensions the continuum limit of ϕ^4 theory appears to be a free field unless a finite cutoff is retained. Viewed as an effective field theory with a cutoff, however, the model is perfectly predictive at low energies, and this modern reading is the one under which the Higgs sector of the Standard Model operates.

3 A band that does not fit the current column

This section reproduces the deferral scenario: by the time the wide equation is issued, the first column is nearly full, the reservation check in the package fails, and the band is carried over rather than overprinting the text. To set the stage we summarize the LSZ reduction formula, which converts the Green functions generated by $\mathcal{Z}[J]$ into scattering amplitudes.

The formula rests on the observation that the full two-point function, whatever the interactions, retains a pole at the physical particle mass m_{ph}^2 , with residue Z , the field-strength renormalization. Near the pole the interacting field behaves like $\sqrt{Z}$ times a free field, and asymptotic particle states can be constructed from it. An n -point Green function with all external momenta pushed onto the mass shell then factorizes into n single-particle poles multiplying the scattering amplitude.

Concretely, one Fourier transforms the connected n -point function, amputates each external leg by multiplying with the inverse full propagator, supplies one factor of $\sqrt{Z}$ per leg, and takes the on-shell limit. What survives is the invariant matrix element $\mathcal{M}$ that enters cross sections. At tree level in ϕ^4 theory the $2 \rightarrow 2$ amplitude is simply $\mathcal{M} = -\lambda$; at one loop it acquires the channel-dependent logarithms computed from the bubble diagrams of the previous section. Beyond one loop the amplitude develops branch cuts demanded by unitarity: the optical theorem relates the imaginary part of the forward amplitude to the total cross section, and checking it order by order is a classic consistency test of the diagrammatic rules. Renormalization-group improvement then resums the channel logarithms into the running coupling evaluated at the scale of the process. The full statement, for n incoming and outgoing particles combined, reads:

Equation (??) is the bridge between the functional formalism and experiment. Everything on the left is computable, order by order, from the diagrams generated by equation (??); everything on the right is measurable, after squaring and integrating against phase space, as a cross section or a decay rate.

Several practical remarks are in order. The field-strength factor Z first differs from unity at two loops in ϕ^4 theory, because the one-loop self-energy is momentum independent; in gauge theories it already appears at one loop. The reduction formula is insensitive to the choice of interpolating field: any operator with a nonvanishing overlap with the one-particle state produces the same S-matrix, a fact that underlies the modern effective-field-theory viewpoint in which fields are mere integration variables.

The same functional technology extends with minor changes to complex scalars, where the source term splits into $J^*\phi + J\phi^*$ and charge conservation forbids correlators with unequal numbers of ϕ and ϕ^* ; to fermions, where the sources become Grassmann valued and the Gaussian integral produces a determinant in the numerator rather than the denominator; and to gauge fields, where the redundancy of the description requires the Faddeev–Popov construction before a propagator even exists. In every case the pattern set by the humble ϕ^4 model persists: a free Gaussian core, an interaction promoted to a differential operator, and diagrams as the bookkeeping of its expansion.

A final word on the status of the perturbative series itself. Dyson’s classical argument shows that the expansion in λ cannot converge: were it convergent in a disc around the origin, the theory would also make sense at small negative coupling, where the potential is unbounded below and the vacuum decays. The series is instead asymptotic, with coefficients growing factorially, and its information content is recovered through Borel summation or, more robustly, through the modern machinery of resurgence, in which the ambiguities of the Borel transform are cancelled by instanton-like contributions.

None of this diminishes the practical value of the expansion. For weak coupling the first few orders approximate the exact answer to an accuracy far beyond experimental reach, and the asymptotic charac-

$$\prod_{k=1}^n \lim_{p_k^2 \rightarrow m_{\text{ph}}^2} \frac{p_k^2 - m_{\text{ph}}^2}{i\sqrt{Z}} \tilde{G}_{\text{conn}}^{(n)}(p_1, \dots, p_n) = \langle p_{\text{out}} | S | p_{\text{in}} \rangle_{\text{amp}} \quad (\text{LSZ reduction, deferred band}) \quad (3)$$

ter only becomes visible at orders comparable to $1/\lambda$. The same structure — divergent series, exponentially small corrections, and their interplay — reappears throughout physics, from the anharmonic oscillator of quantum mechanics to the large-order behaviour of QED, where the corresponding growth was estimated by Lautrup and by Lipatov using precisely the functional methods rehearsed here.

The reader who has followed the thread from equation (??) to equation (??) now possesses the complete conceptual pipeline of perturbative quantum field theory: a path integral defines the theory, functional differentiation generates its correlators, diagrams organize their expansion, renormalization renders them finite, and LSZ converts them into numbers an experiment can check. Every refinement — gauge symmetry, spontaneous breaking, effective actions, anomalies — is a variation on this pipeline rather than a replacement for it.
